Recombination at a defect-rich interface is one of the major efficiency-loss mechanisms in polycrystalline heterojunction thin-film solar cells.\cite{1,2} Cuprous oxide (Cu$_2$O) is considered a promising Earth-abundant semiconductor for thin-film solar cells compatible with terawatt-level deployment.\cite{3–5} However, the power conversion efficiency (PCE) of Cu$_2$O-based solar cells has remained significantly lower than the theoretical single-junction maximum efficiency of $>$20%, often due to low open-circuit voltages ($V_{OC}$) resulting from rapid interfacial recombination.\cite{6–8} This interfacial recombination is believed to originate mostly from i) non-ideal band-alignment with an adjacent n-type transparent conductive oxide (TCO) layer (e.g., Al-doped ZnO or indium-tin-oxide) and ii) a high density of trap states in the region near the heterojunction interface. Various buffer layers including Ga$_2$O$_3$, TiO$_2$, and amorphous zinc-tin-oxide (a-ZTO) have been applied at the junction interface to provide more ideal band alignment.\cite{6,9,10}

To reduce the interfacial trap density and further enhance heterojunction quality, any defects at the heterojunction interface should be minimized.\cite{11} In particular, a cupric oxide (CuO) layer on the Cu$_2$O surface is highly undesirable since it has a smaller bandgap ($E_g \approx 1.4$ eV) than Cu$_2$O ($E_g \approx 2$ eV) and its conduction band energy near 4 eV from the vacuum level can create deep states at the interface, enhancing interfacial recombination.\cite{12,13,14} A CuO layer is formed readily on a Cu$_2$O or Cu surface during quenching and/or exposure to an oxygen-rich ambient.\cite{7,15,16} Similar surface chemistry changes are common for many thin-film solar cell materials including copper indium gallium selenide (CIGS).\cite{17} In the past, chemical treatments have been employed to modify the surface chemistry of air-exposed CIGS films.\cite{18,19} For Cu$_2$O prepared by a thermal oxidation method, similar methods for Cu$_2$O surface modification, including wet etching, heat treatments, and a catalyst layer, have been introduced to remove the CuO surface layers, resulting in enhancements of solar cell performance.\cite{5,7,18} However, even if the surface treatments remove the CuO layer completely, a nanometer-scale-thick CuO layer can re-grow when the surface is exposed to air thereafter.\cite{5} Thus, a surface modification process with high controllability should be performed in situ immediately prior to overlayer deposition during solar cell fabrication (e.g., buffer layer deposition) to achieve higher PCE. Recently, Wilson et al. proposed a method to control interface stoichiometry of Cu$_2$O in situ by controlling the oxygen partial pressure during sputtering of a ZnO over-layer.\cite{14}

Here, we demonstrate a method to tune the chemical state of the interfacial layer of Cu$_2$O absorbers by chemical means, by engineering the atomic layer deposition (ALD) reaction conditions of an a-ZTO buffer layer in an all-oxide thin-film solar cell device architecture (ZnO:Al/a-ZTO/Cu$_2$O). During the past decade, ALD has demonstrated utility in a range of photovoltaic device-processing applications, including buffer-layer deposition and surface passivation.\cite{19,20} The discrete nature of the ALD process enables a high degree of tunability of the layer properties as well as an excellent uniformity over large-scale substrates.\cite{19–21}

We exploit the fact that ALD can involve highly reactive metal-precursors and oxidizers, which can also affect surface chemistry of substrates. We utilize the thermodynamics of the half-cycle reaction in the ALD sequence of a-ZTO buffer layer deposition to control the surface chemistry of as-grown Cu$_2$O thin-film, and describe how this approach could be generalized to other buffer-layer materials. The CuO (Cu$^{2+}$ state) interfacial layer at a-ZTO/Cu$_2$O can be reduced to Cu$_2$O (Cu$^{1+}$ state) by pulsing a Zn precursor, and additional oxidation of Cu$_2$O surface by an oxidant pulse can be suppressed by lowering the ALD reaction temperature. By engineering the surface chemistry associated with the ALD reaction temperature, the chemical state of Cu at the interface can be controlled and a high-quality heterojunction can be formed. We demonstrate the
enhanced performance of CuO-based solar cells by controlling interface chemistry, resulting in an improved $V_{oc}$.

A nanometer-scale-thick surface layer of CuO phase is normally formed on CuO films grown by electrochemical deposition. Figure 1 shows XPS spectra of the Cu-2p core levels for an as-grown CuO film surface and a CuO surface sputtered by argon ions at 1 keV in situ. Peaks at 932.2 and 934.2 eV indicate Cu$^{2+}$ and Cu$^{3+}$ states, respectively.[22,23] Broad satellite peaks near 940–945 eV originate from the CuO phase, which is a characteristic of materials having a d9 configuration in the ground state.[23] Thus, the existence of the satellite peaks is an evidence of formation of the CuO phase in addition to the peak assigned to the Cu$^{2+}$ state at 934 eV. After sputtering the sample surface for 1 min, the signals from the CuO phase disappear and only signals from the Cu$_2$O phase are observed. The XPS spectra with depth profiling suggest that the CuO forms only at the near-surface region of the Cu$_2$O. The CuO is likely due to exposure of the sample to ambient atmosphere, in which an abundance of oxygen can promote the complete oxidation of copper cations to Cu$^{2+}$ (CuO).[21,24] Considering the electron escape depth of ~5 nm and the XPS signal intensity of CuO phase relative to Cu$_2$O phase, the surface CuO layer is expected to have an approximate thickness of only 1 nm, perhaps suggesting that the formation of a thicker surface layer is limited by oxygen diffusion through CuO.

To remove the surface CuO layer and create a high-quality a-ZTO/Cu$_2$O interface, the thermodynamics of the a-ZTO ALD reaction are investigated. The optimized a-ZTO ALD consists of ZnO and SnO$_2$ deposition reactions with a pulse ratio of 3:1.[9,25] The starting sequence is a pulse of diethylzinc (DEZ) as a Zn precursor, followed by a pulse of hydrogen peroxide (H$_2$O$_2$) as an oxidizer. It has been reported that the injection of ALD metal precursors can reduce an underlying layer if the reactions are energetically favorable.[26,27] The Gibbs free energy of reaction ($\Delta G_r$) can predict whether the surface reactions in a-ZTO ALD are spontaneous. Plausible reactions of DEZ with CuO and their $\Delta G_r$ at 373 K are the following:[28]

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + 2\text{CuO} \rightarrow \text{ZnO} + \text{Cu}_2\text{O} + \text{C}_2\text{H}_4 (g) + \text{C}_2\text{H}_4 (g).$$

$$\Delta G_{r,373K} = -341.45 \text{ kJ mol}^{-1} \quad (1)$$

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + 2\text{CuO} \rightarrow \text{ZnO} + \text{Cu}_2\text{O} + 2\text{C}_2\text{H}_4 (g) + \text{H}_2 (g).$$

$$\Delta G_{r,373K} = -249.10 \text{ kJ mol}^{-1} \quad (2)$$

or

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + 2\text{CuO} \rightarrow \text{ZnO} + \text{Cu}_2\text{O} + \text{C}_4\text{H}_{10} (g).$$

$$\Delta G_{r,373K} = -359.12 \text{ kJ mol}^{-1} \quad (3)$$

In addition, the reduction of Cu$_2$O to metallic Cu by DEZ is also possible by the following reactions:

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + \text{Cu}_2\text{O} \rightarrow \text{ZnO} + 2\text{Cu} + \text{C}_2\text{H}_4 (g) + \text{C}_2\text{H}_4 (g).$$

$$\Delta G_{r,373K} = -286.70 \text{ kJ mol}^{-1} \quad (4)$$

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + \text{Cu}_2\text{O} \rightarrow \text{ZnO} + 2\text{Cu} + 2\text{C}_2\text{H}_4 (g) + \text{H}_2 (g).$$

$$\Delta G_{r,373K} = -206.98 \text{ kJ mol}^{-1} \quad (5)$$

or

$$\text{Zn(C}_2\text{H}_5\text{)}_2 + \text{Cu}_2\text{O} \rightarrow \text{ZnO} + 2\text{Cu} + \text{C}_4\text{H}_{10} (g).$$

$$\Delta G_{r,373K} = -317.00 \text{ kJ mol}^{-1} \quad (6)$$

On the other hand, the H$_2$O$_2$ sequence after the DEZ pulse can oxidize Cu$_2$O to CuO by the following reaction:

$$\text{Cu}_2\text{O} + \text{H}_2\text{O}_2 \rightarrow 2\text{CuO} + \text{H}_2\text{O} (g).$$

$$\Delta G_{r,373K} = -228.59 \text{ kJ mol}^{-1} \quad (7)$$

All reactions have negative $\Delta G_r$ at 373 K, indicating that both reduction and oxidation reactions are thermodynamically favorable in the presence of reducing and oxidizing precursors, respectively.

As the thermodynamic analysis predicts, the Zn precursor in the a-ZTO ALD process is experimentally observed to reduce the CuO surface layer to Cu$_2$O. Figure 2a shows normalized XPS spectra of Cu-2p at the Cu$_2$O surface after DEZ and an Sn(II) precursor (1,3-bis(1,1-dimethylethyl)-4,5-dimethyl-(4R,5R)-1,3-diazaestannolidin-2-ylidene) were pulsed on Cu$_2$O films with CuO surface layers. Here, nine super-cycles (three DEZ pulses and one Sn(II) precursor pulse per one super-cycle) of metal precursor injections were used, skipping the injection of H$_2$O$_2$. Two reaction temperatures of 90 and 170 °C were investigated. At both temperatures, the intensities of the CuO peaks decreased after the injection of metal precursors, which indicates that the CuO layer was partially reduced to Cu$_2$O or Cu. The similar decrease in the intensity of the CuO peak for both temperatures suggests that the reduction rate is rapid at both temperatures. A control experiment was performed (the Cu$_2$O samples were kept in the chamber without doing any ALD treatment), which showed negligible change of XPS spectra as shown in Figure S1 (Supporting Information).
When only Sn(II) precursor pulses were introduced to the Cu$_2$O film while not injecting DEZ or H$_2$O$_2$ with the same conditions mentioned above, negligible reduction of the CuO layer was observed. In contrast, the injection of DEZ without any Sn(II) precursor or H$_2$O$_2$ significantly decreased the intensity of the CuO peak. Thus, the reduction of the CuO layer is mainly driven by DEZ, forming a stable ZnO without the aid of the oxidant (Figure 2 b). The reduction of Cu$_2$O by the Sn(II) precursor is thermodynamically or kinetically unfavorable. Interestingly, the reduction of CuO is most effective when only DEZ was introduced without any Sn(II) precursor, which suggests the surface-adsorbed Sn(II) precursor inhibits further adsorption of DEZ. The reduction of CuO is possible by the reactions of DEZ to form ZnO as described in Reactions 1–6. Figure 2 b shows the XPS spectra of Zn-2p core levels after a pulse of only DEZ molecules on a Cu$_2$O film at 90 °C, showing the same Zn-2p core levels as a ZnO film grown by ALD using DEZ and H$_2$O$_2$. c) The Cu-LMM Auger spectra from Cu$_2$O and metallic Cu after the growth of a-ZTO layer by ALD at 90 °C. 20-nm-thick Cu film was prepared by e-beam evaporation at room temperature for the comparison. d) XPS spectra of Cu-2p core levels with 10-nm-thick a-ZTO films deposited on Cu$_2$O at reaction temperatures between 90 and 170 °C, showing no signal from elemental Cu for all temperatures, which indicates no Cu diffusion occurred.

Although both reduction reactions to Cu$_2$O and metallic Cu are thermodynamically possible, metallic Cu is not detected after the metal precursor injections. It is difficult to distinguish Cu$^{1+}$ from metallic Cu by XPS, because the peak positions of Cu-2p from the both states are close. Instead, Cu$_2$O and Cu metal can be distinguished from the Cu-LMM Auger transition kinetic energy. The Cu-LMM kinetic energies from Cu$_2$O and metallic Cu have been reported to be 916.5 and 918.4 eV, respectively, with Al-K$_\alpha$ radiation when the peaks were referenced to the C-1s binding energy at 284.6 eV. As shown in Figure 2 c, a kinetic energy of 916.9 eV is observed when the CuO phase was reduced by DEZ during the a-ZTO ALD process. Both the peak position and shape are closer to the signal from Cu$_2$O than from metallic Cu. To compare with the signal from the metallic Cu phase, a 20-nm-thick metallic Cu film was deposited by e-beam evaporation at room temperature and an a-ZTO film was grown on the Cu film. Obviously, the metallic Cu is observed at 919 eV, as well as a peak from the Cu$_2$O phase (formed by air exposure of Cu film after the growth) at 917 eV. The metallic Cu phase was detected successfully by XPS in the a-ZTO/Cu sample, owing to the a-ZTO layer protecting the Cu surface from the further oxidation by air. However, no metallic Cu phase was observed in the a-ZTO/Cu$_2$O sample. This indicates the formation of Cu may be limited kinetically.
at the a-ZTO/Cu₂O sample, although the thermodynamic criteria for the formation of Cu are satisfied according to the Reactions 4–6. In addition, we investigated the potential for Cu diffusion through a-ZTO layers, since any trace of metallic Cu is known to pose significant diffusion issues as experienced in Cu-related processes of various semiconductor applications.  

10-nm-thick a-ZTO films, thicker than an electron escape depth of ~5 nm in XPS, were deposited on Cu₂O at reaction temperatures between 90 and 170 °C. No signal from Cu is detected by XPS for all temperatures shown in Figure 2d. The Auger signal and the Cu-diffusion investigation did not indicate any trace of metallic Cu, which suggests that Reactions 4–6 are limited by high activation energies (slow kinetics).

On the other hand, H₂O₂ exposure after the DEZ sequence can re-oxidize the Cu₂O surface layer to CuO. Figure 3 shows the normalized XPS spectra of Cu-2p for three different Cu₂O samples: an as-grown Cu₂O film and H₂O₂-exposed Cu₂O films deposited at reaction temperatures of 70, 90 and 170 °C. Here, 36 H₂O₂ pulses were introduced to the Cu₂O samples, which is equal to the total H₂O₂ pulses of nine super-cycles. The increased satellite peak intensities at 940–945 eV for both temperatures indicate that the surface of the Cu₂O film is partly re-oxidized to CuO by H₂O₂. As the reaction temperature is raised from 70 to 170 °C, the intensity of the Cu²⁺ peak at 934 eV is increased relative to the Cu¹⁺ peak at 932 eV. This result suggests that more oxidation of Cu₂O to CuO occurs at higher ALD temperatures.

Since the reduction and oxidation reactions possess different temperature dependences, the surface chemistry of Cu₂O films can be controlled by changing the reaction temperature. To investigate the chemical state of Cu at the a-ZTO/Cu₂O interface by XPS, 3-nm-thick a-ZTO films were grown on Cu₂O films at different reaction temperatures in the range of 70–170 °C. Figure 4a shows the normalized XPS spectra of Cu-2p from the a-ZTO/Cu₂O samples. The Cu²⁺ peak at 934 eV is not detected in samples with ALD reaction temperatures below 120 °C. This result suggests that the a-ZTO ALD process itself can effectively reduce the detrimental CuO layer to Cu₂O. However, at the reaction temperature of 170 °C, a small peak shoulder near ~934 eV is observed. The peak shoulder is further investigated by deconvoluting the spectrum into multiple peaks as shown in Figure 4b. The peak shoulder is attributed to the Cu²⁺ state centering at ~933.7 eV. As discussed in the previous experiments, a higher reaction temperature could increase the oxidation rate by H₂O₂ significantly, while the reduction rate by DEZ was not affected in the temperature range between 90 and 170 °C. Thus, it can be concluded that the oxidation reaction by H₂O₂ competes with the reduction reaction by DEZ in the a-ZTO ALD process. As the reaction temperature increases, the oxidation reaction becomes faster than the reduction reaction, possibly due to different activation energies. It should be noted that the CuO formation by H₂O₂ is likely diffusion-limited by the a-ZTO layer: the oxidation by H₂O₂ becomes weaker as the a-ZTO layer gets thicker; thus the a-ZTO layer appears to protect the Cu₂O layer from further oxidation by H₂O₂. The Cu²⁺...
possibly due to a CuO layer formed on the Cu$_2$O surface. The layer growth, all processing parameters were identical for all discussed. Except for the ALD temperature of the a-ZTO buffer layer started with the injection of DEZ as electrochemically-deposited Cu$_2$O. Here, the first ALD reaction at 120°C shows slightly darker color than the other devices, possibly due to a CuO layer formed on the Cu$_2$O surface. The devices were completed by coating Al top-electrodes (1 µm) and MgF$_2$ anti-reflective layers (95 nm).

As the analysis of ALD reactions predicted, decreasing the ALD temperature enhances the solar-cell device performance. Current-density vs. voltage ($J-V$) characteristics of the devices were measured under 1-sun (AM 1.5G, 100 mW cm$^{-2}$) illumination conditions as shown in Figure 5b. While the short-circuit current densities ($J_{SC}$) remain between 7 and 8 mA cm$^{-2}$, the $V_{OC}$ shows a strong dependence on the a-ZTO ALD temperature. The changes of $V_{OC}$ and PCE of the devices are summarized as a function of the a-ZTO ALD temperature in Figure 5c. By decreasing the ALD temperature down to 50 °C, $V_{OC}$ increases up to 0.65 V. However, the devices with ALD temperatures over 150 °C show a significant reduction of $V_{OC}$ below 0.3 V. This drastic change can be explained by the increase of CuO content at higher ALD temperatures, increasing defect density at the a-ZTO/Cu$_2$O interface. The highest PCE of 3.06% is achieved with an a-ZTO ALD temperature of 70 °C. The device with an ALD temperature of 50 °C shows the highest $V_{OC}$, but its reduced fill-factor results in a lower PCE.

The possibility of bulk Cu$_2$O thermal degradation was ruled out by an additional experiment. A heat treatment of a Cu$_2$O layer at 150 °C before a-ZTO deposition at 70 °C was performed. The heat-treated device showed performance comparable to the device made without the heat treatment (Figure S2, Supporting Information), suggesting that the high temperature during a-ZTO deposition degrades only the heterojunction interface.

The heterojunction quality of the fabricated devices is further investigated by measuring capacitance vs. frequency ($C-f$) characteristics as shown in Figure 5d. A direct-current bias of 0 mV and an alternating-current bias of 10 mV were applied at room temperature. At high frequencies near 1 MHz, all devices show capacitances converging to 3–5 nF cm$^{-2}$, which is close to a simple geometric capacitance ($C_g = 2.7$ nF cm$^{-2}$) due to dielectric freeze-out. At low frequencies, on the other hand, the capacitances plateau to a depletion capacitance ($C_d$), which is dominated by the energy levels and densities of interfacial and bulk defects in the depleted region.$^{[4]}$ As the ALD temperature
Atomic Layer Deposition of a-ZTO Thin Films: The a-ZTO thin-films were deposited using a custom-built cylindrical ALD reactor with a sample stage 30 cm long and 3 cm wide, and a chamber volume of 0.627 L. The aluminum substrate stage and the entire wall of ALD chamber were kept at the same ALD reaction temperature inside a Lindberg Blue M tube furnace (Thermo Scientific). Diethylyzinc (Sigma Aldrich) and 1,3-bis(1,1-dimethylethyl)-4,5-dimethyl-(4R,5R)-1,3-diazastannolidin-2-ylidene were used as Zn and Sn precursors, respectively. The Zn and Sn precursors were kept at constant temperature of 25 and 40 °C, respectively. A H2O2 solution (50 wt% in H2O, Sigma Aldrich) was used as a common oxidant for a-ZTO growth to enable the ALD reaction with the Sn(II) precursor at reaction temperature below 170 °C, which was not possible by using H2O. Due to a high vapor pressure of H2O2, as-received H2O2 solution was placed in a glass container held at 25 °C and it was vaporized into a trap, which is made of stainless steel with a volume of 35 mL, prior to the release into the ALD reactor. One super-cycle of a-ZTO consisted of ZnO and SnO2 sub-cycles with a ratio of 3:1. During the each sub-cycle, the exposures of diethylyzine, tin precursor, and H2O2 were estimated to be approximately 0.32, 0.033, and 0.027 Torr s, respectively. Further details on electrical, structural, and optical properties of a-ZTO films grown by ALD are described elsewhere.[9,23]

Solar Cell Fabrication: A 200-nm-thick Au bottom-electrode with 5-nm-thick Ti adhesion layer was deposited on a 1 × 1 inches2 SiO2 by e-beam evaporation. To define a cell area of 3 × 3 mm2, a 2.5-µm-thick SiO2 layer was deposited by plasma-enhanced chemical vapor deposition and areas defined by photolithography were etched by a buffered-oxide-etchant (7:1, J. T. Baker). A 2.5-µm-thick Cu2O film was deposited on the exposed Au area at 40 °C by the galvanostatic electrochemical method.[9,14,13] A lactate-stabilized copper sulfate aqueous solution was prepared with 3 M lactic acid (Sigma Aldrich), 0.2 M cupric sulfate pentahydrate (CuSO4·5H2O, Sigma Aldrich) and de-ionized water (18.3 MΩ cm, Ricca Chemical), and then 2 M sodium hydroxide (NaOH, Sigma Aldrich) aqueous solution was added to adjust the pH of the solution to 12.5. All reagent-grade chemicals were used and the solution was filtered and stirred thoroughly. A constant current density of 0.23 mA cm−2 was applied for 2 h using a Keithley 2400 source meter with a Pt counter electrode to grow the Cu2O films. The Cu2O film surfaces were rinsed with de-ionized water. The a-ZTO and ZnO:Al thin-films were deposited by ALD as described in detail elsewhere.[9,16] 1-µm-thick Al top-electrodes were deposited by e-beam evaporation with a grid spacing of 0.5 mm defined by a lift-off process. A 95-µm-thick MgF2 film as an antireflective layer was deposited by thermal evaporation.

Characterization: Surface morphologies of the devices were analyzed using a Ultra 55 FESEM (Zeiss). XPS measurements were performed using a K alpha XPS (Thermo Scientific). Samples were etched in situ by an Ar ion beam for a depth profiling. The J−V and the C−f characteristics of the devices were measured by using Agilent 4156C and Keithley 2400 semiconductor characterization systems. The standard 1-sun illumination was generated by a Newport Oriel 91194 solar simulator with a 1600 W ozone-free Xe-lamp with a AM1.5G filter and a Newport

![NREL X25 IV System](image)

**Figure 6.** NREL certified J−V characteristics of the best device, with an a-ZTO buffer layer grown at 70 °C, under 1-sun (ASTM G173 global) illumination.

For a-ZTO decreases from 120 to 70 °C, the capacitance at 1 kHz decreases from 42.7 to 35.9 nF cm−2, which suggests reduced Cu4+-related defect densities at the a-ZTO/Cu2O interface. However, the ALD temperature of 50 °C shows a higher capacitance than that of 70 °C, possibly due to bulk defects in the a-ZTO layer. Too-low ALD reaction temperature often results in increased carbon and nitrogen-related impurities, which might be mitigated with plasma-assisted ALD.[12,33]

The device with the highest efficiency was characterized independently at the National Renewable Energy Laboratory (NREL). The J−V characteristic of the device under the ASTM G173 global 1-sun illumination is shown in Figure 6. The device was measured on a temperature-controlled stage, after a 10-minute light-soak at the maximum power condition (a device was measured on a temperature-controlled stage, after a 10-minute light-soak at the maximum power condition). The capacitance at 1 kHz of 2.85% is shown in Figure S3, Supporting Information. The CuO surface layer is formed by air exposure. Starting the first ALD process to reduce this layer to Cu2O, enhancing the electrical, structural, and optical properties of a-ZTO films grown by ALD can be controlled and the formation of a high-quality heterojunction is demonstrated. The controlled interface chemistry increases the VOC of a-ZTO/Cu2O solar cells, resulting in an independently verified PCE of 2.85%. This approach may also be useful in other material systems that employ ALD overlayers (buffer layers and TCOs), to improve interface quality by engineering cation chemical states locally at the interface.

Experimental Section

Atomic Layer Deposition of a-ZTO Thin Films: The a-ZTO thin-films were deposited using a custom-built cylindrical ALD reactor with a sample stage 30 cm long and 3 cm wide, and a chamber volume of 0.627 L. The aluminum substrate stage and the entire wall of ALD chamber were kept at the same ALD reaction temperature inside a Lindberg Blue M tube furnace (Thermo Scientific). Diethylyzinc (Sigma Aldrich) and 1,3-bis(1,1-dimethylethyl)-4,5-dimethyl-(4R,5R)-1,3-diazastannolidin-2-ylidene were used as Zn and Sn precursors, respectively. The Zn and Sn precursors were kept at constant temperature of 25 and 40 °C, respectively. A H2O2 solution (50 wt% in H2O, Sigma Aldrich) was used as a common oxidant for a-ZTO growth to enable the ALD reaction with the Sn(II) precursor at reaction temperature below 170 °C, which was not possible by using H2O. Due to a high vapor pressure of H2O2, as-received H2O2 solution was placed in a glass container held at 25 °C and it was vaporized into a trap, which is made of stainless steel with a volume of 35 mL, prior to the release into the ALD reactor. One super-cycle of a-ZTO consisted of ZnO and SnO2 sub-cycles with a ratio of 3:1. During the each sub-cycle, the exposures of diethylyzine, tin precursor, and H2O2 were estimated to be approximately 0.32, 0.033, and 0.027 Torr s, respectively. Further details on electrical, structural, and optical properties of a-ZTO films grown by ALD are described elsewhere.[9,23]

Solar Cell Fabrication: A 200-nm-thick Au bottom-electrode with 5-nm-thick Ti adhesion layer was deposited on a 1 × 1 inches2 SiO2 by e-beam evaporation. To define a cell area of 3 × 3 mm2, a 2.5-µm-thick SiO2 layer was deposited by plasma-enhanced chemical vapor deposition and areas defined by photolithography were etched by a buffered-oxide-etchant (7:1, J.
